## Abstract

In the Sahel very high temperatures prevail in Spring, but little is known about heat waves in this region at that time of year. In this study we document Sahelian heat waves with a new methodology that allows selecting heat waves at specific spatio-temporal scales and can be used in other parts of the world. It is applied separately to daily maximum and minimum temperatures, as they lead to the identification of distinct events.

Synoptic to intraseasonal Sahelian heat waves are characterized from March to July over the period 1950-2012 with the Berkeley Earth Surface Temperature (BEST) gridded dataset.

Morphological and temperature-related characteristics of the selected heat waves are presented. From March to July, the further into the season, the shorter and the less frequent the heat waves become. From 1950 to 2012, these synoptic to intraseasonal heat waves do not tend to be more frequent; but however they become warmer, and this trend follows the Sahelian climatic trend.

Compared to other commonly used indices, the present index tends to select heat waves with more uniform intensities. This comparison of indices also underlined the importance of the heat index definition on the estimated climatic heat wave trends in a changing climate.

Finally, heat waves were identified with data from three meteorological reanalyses: ERA-Interim, MERRA and NCEP2. The spreads in temperature variabilities, seasonal cycles and trends among reanalyses lead to differences in the characteristics, interannual variability and climatic trends of heat waves, with fewer departures from BEST for ERA-Interim.

# 1. Introduction

From April to June, the sub-tropical Sahelian region experiences very high temperature during both nighttime and daytime, when monthly-mean temperatures can range up to 30 and 40°C respectively. At the same time, regional warming over the Sahel in the past 60 years reaches +1.5°C over April-May (Guichard et al. 2015). In April 2010, a huge heat wave hit the Sahel resulting in numerous deaths, mostly among children and elderly (Azongo et al. 2012; Diboulo et al. 2012). According to Mora et al. (2017), the Sahel is exposed to deadly temperature conditions around one third of the year, making it one of the regions with the most severe temperature conditions. The risk of these temperature hazards is enhanced by the fact that the Sahelian population is increasing very quickly: Nigeria should become the 3<sup>rd</sup> largest country in the world by 2050, reaching 410 millions, while by 2100 the population of Niger is projected to increase by at least a factor of nine, from 21 millions in 2017 to 192 millions in 2100 (Garenne and Ferdi 2016; United Nations Department of Economic and Social Affairs/Population Division 2017). Thus superimposed on this hot climate, heat wave events in this region at this time of the year may have particularly severe impacts on health, and also potentially on ecosystems, transportation or agriculture (Sheehy et al. 2005; Sultan et al. 2013).

Impactful heat waves have been reported across the globe, from Chicago in 1995 to Southeast Australia in 2009. Western Europe suffered heavy human losses during the 2003 heat wave event to which 70 000 deaths are attributed (Coumou and Rahmstorf 2012); Russia's death toll reached more than 50 000 during the 2010 heat wave (McMichael and Lindgren 2011). In recent years, these events led to an increasing number of studies on how to define, characterize, understand and predict

heat waves. Because of climatic trends toward higher temperatures, their observed and future changes were also discussed: heat waves are expected to be more frequent, longer, and hotter, and cover a larger area (Cowan et al. 2014; Russo et al. 2014; Schoetter et al. 2015). Climate and heat wave temperature trends do not necessarily increase at the same rate: in their analysis of the heat waves in a changing climate, Gershunov and Guirguis (2012) pointed out that the ratio between the temperature mean and extremes of California's inlands decreased over the period 1850-2010. In this case, the climatic trend is thus stronger than the heat wave trend. Argüeso et al. (2016) showed that the climatic change in temperature variability has a major influence on the heat wave changes over some parts of Europe and the USA. However, they also emphasize that this finding is not valid in tropical regions where the mean seasonal warming explains most of these changes.

To date, most climatological heat wave studies have focused on Europe (e.g. Meehl and Tebaldi 2004; Fischer and Schaer 2010; Stefanon et al. 2012; Schoetter et al. 2015), Australia (e.g. Perkins et al. 2012; Nairn and Fawcett 2013; Perkins and Alexander 2013; Cowan et al. 2014), the USA (e.g. Robinson 2001; Meehl and Tebaldi 2004; Gershunov and Guirguis 2012; Mutibwa et al. 2015), or Asia (e.g. Ito et al. 2013; Lee and Lee 2016) while only very few concern the Sahel (e.g. Fontaine et al. 2013; Déqué et al. 2016). Some studies assess heat waves from a global perspective, however they often do not show any results for West Africa (Zhang et al. 2011; Russo et al. 2014) partly due to the scarcity of in-situ observations. Thus Sahelian heat waves still need to be further documented and explained; the present paper addresses this overall objective.

To be able to identify meteorological situations associated to such events, the first question that arises is how to define and detect a heat wave. A heat wave generally corresponds to a prolonged period of particularly high or extreme

temperatures. The Expert Team on Climate Change Detection, monitoring and Indices (ETCCDI) published a list of core indices ([http://etccdi.pacificclimate.org/list\\_27\\_indices.shtml](http://etccdi.pacificclimate.org/list_27_indices.shtml)) to measure temperature extremes based on a single characteristic, for instance a frequency of occurrence of warm nights or an intensity of the maximum daily maximum temperature across the year. Every metric is relevant to particular applications. Other studies make use of indices that detect “heat wave objects” in space and time, and analyze the characteristics of these objects. Each of these studies generally develops its own specific definition. However, as highlighted by Perkins (2015), these definitions have some common features: temperature is always used in a raw or processed form, most of the times combined with a percentile-type threshold and a minimum duration of the heat wave is often considered. Most studies use the daily maximum temperature (Fischer and Schaer 2010; Stefanon et al. 2012; Schoetter et al. 2015) or separately analyze daily minimum and maximum temperatures, hereafter referred to as Tmin and Tmax (Gershunov and Guirguis 2012; Perkins et al. 2012; Fontaine et al. 2013; Perkins and Alexander 2013; Mutibwa et al. 2015). Robinson (2001) and Willett and Sherwood (2012) use a heat index accounting for both temperature and humidity effects (respectively relative humidity and vapor pressure). The vast majority of the studies use a percentile, very often the 90<sup>th</sup> percentile, as the lower-limit over a moving time window. By design, the methods using a moving time window detect heat waves throughout the year in a uniform way. The minimum duration of heat waves is also often defined to be three days.

In this study, we will define a heat index which follows the basic metrics described above in order to identify Sahelian heat waves from March to July, i.e., during the hottest months of the year. We also aim at defining Sahelian heat waves as large-scale meteorological events, coherent in space and time, arising as strong

and rapid departures of temperature at synoptic to intraseasonal scales. We then predominantly focus on meteorological scales rather than other signals such as interannual fluctuations, annual cycles and climatic trends. In other words, as in Gershunov and Guirguis (2012) and Stefanon et al. (2012), we consider heat waves as occurring in a non-stationary climate. One more motivation to remove the climatic trends is that thresholds based directly on temperatures are expected to be exceeded more often due to the mean climatic warming. The heat wave detection is based either on Tmax or Tmin, because processes controlling daytime and nighttime temperatures in the Sahel are likely to be distinct: for instance, maximum temperature is often influenced by the incoming surface shortwave radiation whereas the minimum temperature is very sensitive to the amount of water vapor during this time of the year (Guichard et al. 2009; Slingo et al. 2009; Gounou et al. 2012; Largeron et al. 2017). Another noteworthy difference for this heat index is that the percentile is fixed over the whole March to July period instead of over a moving window: it enables a seasonal analysis of the heat wave occurrence. Although large-scale atmospheric phenomena or modes of climatic variability are not studied in this paper, our results should be valuable for further studies addressing this topic, in the Sahel as well as in other regions.

The methodology used to build our heat index and to study meteorological heat waves over the Sahel in Spring is explained in section 2. Section 3 presents the climatological characteristics of these heat waves, including their frequency, duration, intensity and spatial extent. Benefits and limits of the present heat wave definition are further discussed in section 4, via a comparison with other definitions. An assessment of the sensitivity of the results across different temperature datasets (including three meteorological reanalyses) is also presented. Finally, section 5

emphasizes the evolution of heat wave properties over the recent historical period and compares it to regional warming. Conclusions are given in section 6.

## 2. Datasets and methodology

### a. Datasets

We use daily minimum and maximum temperature datasets provided by one observationally-based gridded product and retrieved from three meteorological reanalyses over [0°N 40°N] [-20°E 40°E], hereafter referred to as the African domain.

These datasets are:

- The Berkeley Earth Surface Temperature (BEST, Rohde et al. 2013, 2014), which provides data on a 1° × 1° grid from 1880 until recent years. We consider the period 1950-2012 as observations in the Sahel are very few prior to 1950.

- The European Center for Medium-Range Weather Forecasts (ECMWF) Interim Re-Analysis (ERA-Interim, Dee et al. 2011) over 1979-2012 on a 1° × 1° grid.

- The National Centers for Environmental Prediction (NCEP) – Department of Energy AMIP-II reanalysis (NCEP2, Kanamitsu et al. 2002) over 1979-2012 on a 2° × 2° grid.

- The Modern-Era Retrospective Analysis for Research and Applications reanalysis (MERRA, Rienecker et al. 2011) from National Aeronautics and Space Administration's Global Modeling and Assimilation Office over 1979-2012 on a 0.5° × 0.66° grid.

The use of several datasets is motivated by the fact that data are sparse in the Sahel. The Berkeley Earth website provides historical values of the number of stations used in their dataset at regional, national and local scales. For instance in Mali (<http://berkeleyearth.lbl.gov/regions/mali>), around 10 stations from inside the country, and 100 stations from the neighborhood regions are used. The numbers of stations used are not constant in time, with less stations prior to 1950. Thus the influence of distinct physical parametrizations and assimilation procedures in the three reanalyses, as well as the interpolation method used in BEST, are all likely to induce differences in surface temperatures. The main differences are documented in Appendix A and briefly summarized below.

BEST and the three reanalyses were compared over 1979-2010 to two SYNOP stations with consistent long-time temperature series: Hombori, Mali (15.33°N, 1.8°E) (Guichard et al. 2015, Fig. A1) and Niamey, Niger (13.48°N, 2.17°W) (Leauthaud et al. 2016, not shown). Observations from both stations are included in BEST, but the time series of Hombori used by BEST has many gaps, especially over the recent years. The dataset we used was enhanced and quality checked by Mougin and collaborators from the Mali Meteorological Agency from paper archives (Guichard et al. 2015). In addition, BEST, ERA-Interim, NCEP2 and MERRA were compared over [10°N 20°N] [-10°E 20°E], hereafter referred to as the Sahelian domain (Fig. A2). Numerous differences are found between datasets; their magnitudes fluctuate from month to month. As may be expected from its construction, BEST is the closest to these two SYNOP stations in terms of monthly and seasonal mean. BEST is constructed by kriging (interpolating) in-situ data, notably including SYNOP stations. Away from the observations, BEST might be less accurate. On average, in NCEP2 Tmax and Tmin are both too low (e.g., by more than 3°C in April for Tmin), while Tmax is too high in MERRA and too low in ERA-

Interim (Fig. A1a and A2a). In NCEP2, the seasonal cycle is shifted by about one month (Fig. A1b and A2b) and the Tmin variance is largely overestimated (Fig. A1c and A2c). The Tmax variance is generally higher in the three reanalyses than in BEST, without any clear link between the grid-size of the reanalysis and the magnitude of the variance (Fig. A1c and A2c). The distributions are most of the time skewed to the left, especially for Tmax in April and May (Fig. A1d and A2d): this negative skewness highlights the predominance of time sequences of relatively similar warmer days, interrupted by less frequent but much cooler days. It also suggests that physical and dynamical mechanisms constrain Tmax upper extrema.

Following these comparisons, BEST is hereafter set as the reference. Furthermore, its historical depth, going back to 1950, enables trend computation over longer time periods than 1979-2012. Differences between the various databases go further than a mean shift, therefore one may expect differences between detected heat waves (see subsection 4b).

## **b. Heat wave detection**

Temperature fluctuates at climatic, multi-decadal and annual time scales as well as at intraseasonal and synoptic scales, and also within the diurnal cycle. We focus on heat waves corresponding to intraseasonal fluctuations of temperature, which can be defined as strong and rapid temperature departures from its annual cycle.

Following approaches that are commonly used to detect and document the synoptic and intraseasonal variability of the West African monsoon (Janicot et al. 2011; Roehrig et al. 2011; Poan et al. 2013), our heat wave detection is based on temperature anomalies from the slow variations of the annual cycle—variations which are modulated by interannual, multi-decadal or longer-term variabilities. These

anomalies are computed using a 90-day high-pass spectral filter applied on the 1950-2012 temperature-time series. A spectral analysis of Tmin and Tmax time series over the Sahelian domain (not shown) revealed three peaks of energy at the periods 365, 185 and 123 days, consistent with the shape of the mean annual cycle over the region having two maxima, one in Spring and one in Autumn in relation with the annual cycle of the insolation and monsoon precipitation (Guichard et al. 2009). The 90-day filter allows removing the annual cycle of temperature, as well as its modulation at longer timescales. The diurnal cycle is dealt with by studying maximum and minimum temperatures separately.

The heat wave detection includes four distinct operations: 1) a filtering of the low frequencies, 2) a selection of the strongest temperature anomalies, 3) a removal of the short-lived, small and scattered heat waves because we want to focus on relatively large-scale events, and 4) a geographical selection of the heat waves by keeping only those found in the Sahel. The different steps are detailed below and illustrated with the results obtained for the year 1992 with Tmax at a grid point roughly located at the center of the Sahelian domain (Fig. 1).

1. **Filtering:** at each grid point on the African domain for the total period, Tmax and Tmin anomalies are computed using a 90-day high-pass filter (Fig 1a,b).
2. **Selection of hottest days:** for each grid-point, a day is considered "hot" if the local temperature anomaly exceeds the 90th percentile of the distribution over 1950-2010 for March-July (red shading). Such days are identified with a binary heat index (depicted by red dots in Fig. 1c).
3. **Removal of small and short heat waves:** this is done via the sequential application of spatial and temporal constraints. The running order of the spatio-temporal constraint matters, as emphasized by Schoetter et al. (2015).

Here, we chose to apply the spatial constraint before the temporal one as this is more suitable for studying propagating heat waves.

a) **Spatial constraint:** a connectedness constraint based on a region growing technique (Petrou and Bosdogianni 2004; Fiolleau and Roca 2013) is applied to identify and label each connected element, which is discarded when its area covers less than  $60 \times 10^4$  km<sup>2</sup>. This constraint removes numerous small-scale events. This surface threshold corresponds to approximately 20% of the Sahelian domain. For each day, the occurrence of a heat wave in the Sahelian domain is indicated by a black dot in Figure 1d.

b) **Temporal constraint:** the minimum duration of the heat waves is set to 3 days. The impact of this constraint is illustrated in Figure 1e with several heat waves removed in July and a few in March, May and June (compare Fig. 1d and Fig. 1e).

4. **Sahel domain selection:** finally, we only keep heat waves occurring over the Sahelian domain via the labeling done by the connectedness constraint (Fig. 1f) and define the month a heat wave belongs to by its median date. An example of the spatial structure and time evolution of a detected heat wave is given in the bottom of Figure 1.

The final binary heat wave index is called Hlmax (respectively Hlmin) for Tmax (respectively Tmin), while the heat waves finally detected are generically referred to as HWmax (respectively HWmin). The results are not very sensitive to small changes in the prescribed criteria (not shown). Note that this methodology can be applied to any region in the world simply by changing the selected domain on the final step.

260 The spatial constraint corresponds to approximately 2.5% of the large African  
261 domain, and for both heat wave types, 55% of all the March to July periods studied  
262 from 1950-2012 were affected. In other words, a HWmax (HWmin) happens every  
263 two days on average somewhere in Africa. In theory, there can be more than one  
264 heat wave simultaneously present in different regions on a given day. In practice,  
265 over the African domain, around 20% of heat wave days are affected by two  
266 geographically distinct heat waves, and around 2.5 % by three or more events. The  
267 numbers of time-overlapping heat waves is reduced substantially when selecting  
268 heat waves over the smaller Sahelian domain: among the total number of days  
269 during which a heat wave was present (1007 days for HWmax and 871 for HWmin),  
270 only a very few of them were affected by two heat waves (7 for HWmax and 4 for  
271 HWmin).

### 272 **c. Other heat wave indices**

273 In order to analyze the impact of the heat wave definition and to compare our  
274 results with those obtained with indices commonly found in the literature, three other  
275 heat wave indices are considered. These indices differ in the first two steps of the  
276 methodology presented above, namely the temperature filtering and the selection of  
277 the hottest days (definition of the 90<sup>th</sup> percentile).

- 278 • 15DW: many heat wave studies use a relatively shorter moving window to  
279 compute a seasonally-dependent threshold for their detection algorithm: a 5-  
280 day window (e.g., Fontaine et al. 2013; Mutibwa et al. 2015), a 15-day  
281 window (e.g., Fischer and Schaer 2010; Perkins et al. 2012; Perkins and  
282 Alexander 2013; Cowan et al. 2014), or a 31-day window (e.g., Russo et al.  
283 2014). We test the impact of a 15-day moving window to define a seasonal-

dependent 90<sup>th</sup> percentile instead of our constant 90<sup>th</sup> percentile. The 90-day high-pass filter is kept.

- NoFilter\_15DW: as in most heat wave detection algorithms, we use unfiltered raw temperatures and a threshold based on the 90<sup>th</sup> percentile computed using a 15-day moving window centered on the current calendar day (Fischer and Schaer 2010; Perkins et al. 2012; Perkins and Alexander 2013; Cowan et al. 2014).
- NoFilter: this uses raw temperatures and a fixed percentile threshold for the whole period (March-July), as in Schoetter et al. (2015) and Ouzeau et al. (2016).

#### **d. Heat wave metrics**

Heat wave studies commonly focus on three main features: intensity, duration and frequency (Perkins 2015), which can be computed based at the event scale or for each grid-point. Here we use the event-based approach. We also add the spatial extension to these usual features. Besides the frequency of events per year, we grouped the features into two different types of characteristics, the first one relates to morphological properties while the other gathers the temperature-related characteristics.

Morphological characteristics are:

1. Duration of the heat wave in days.
2. Mean area covered in the Sahelian domain, expressed as a percentage relative to this domain. It is computed for each day of the heat wave and averaged over these days.

Temperature variables are:

1. Tmax, Tmin, and daily mean temperature Tmean, defined as  $T_{mean} = (T_{max} + T_{min})/2$ .

2. Tmax and Tmin anomalies (i.e. the 90-day high-pass filtered temperatures).

3. The diurnal temperature range  $DTR = T_{max} - T_{min}$ .

Each of these variables is averaged over the heat wave space and time dimensions.

Decadal trends of the heat waves' characteristics are computed by first averaging the heat wave characteristics each year, either over the whole period (March-July) or over the core hottest spring months (April-May). The yearly mean temperature-related characteristics of heat waves correspond to weighted averages. More precisely, for each heat wave we weighted the averaged value by the area and the duration of the heat wave so that the contribution of heat waves is proportional to their size and duration. Then a linear regression analysis of the yearly mean series is performed and the retrieved multi-decadal trend is considered significant if the associated p value is lower than 0.05. For comparison with changes occurring at larger scales, decadal climatic trends of Tmin and Tmax are computed similarly over the Sahelian domain.

### **3. Morphology and intensity of Sahelian heat waves**

A chronology of the Sahelian heat waves detected as described in section 2 (HWmax and HWmin) is shown in Figure 2 from March to July for the period 1950-2012. About 3.3 HWmax and 2.9 HWmin per year are detected. Only 20% of them

occur simultaneously (crosses in Fig. 2), meaning that in terms of Tmin and Tmax they impact a region larger than 20% of the Sahelian domain for more than 3 consecutive days. This underlines the importance of distinguishing heat waves characterized by high Tmin from heat wave characterized by high Tmax in the Sahel. On average, HWmax cover 42% of the Sahelian domain or  $126 \times 10^4$  km<sup>2</sup>, last 5 days and reach a mean temperature anomaly of 3°C. HWmin have similar mean characteristics except for a slightly smaller area of  $118 \times 10^4$  km<sup>2</sup>. HWmin and HWmax events are evenly distributed across the 1950-2012 period, with no evident trend of their frequency of occurrence (see section 5 for more details) as expected from the filtering process which notably induces a detrending of the data. Moreover these frequencies of occurrence display a strong interannual variability, up to sixfold (see for instance the differences between years 1986 and 1987 for HWmax in Fig. 2).

From a seasonal point of view, the further into the season, the shorter and the less frequent the heat waves become (Fig. 2, 3a,b). This result is consistent for both heat wave types, but slightly more pronounced for HWmin during the end of Spring, in June and July. There is on average less than one HWmin every five years in these two months, while HWmax events are twice as frequent in this period of the year even though they are quite rare compared to early Spring (Fig. 3a). In both cases, their mean temperature anomaly is also weaker than in March (Fig. 3d,e), consistent with lower variability of temperatures anomalies in June-July than in March-April (Fig. A1e and A2e).

In early Spring, mid-latitude synoptic disturbances, e.g., cold surges (Knippertz and Fink 2006; Vizzy and Cook 2009) and the northward progression of the Inter Tropical Discontinuity (ITD, which corresponds to the narrow interface at the surface between warm moist southwesterly monsoon flow and the much hotter and drier northeasterly wind from the Sahara Desert, Lele and Lamb 2010) strongly

modulate the amplitude of surface air temperatures fluctuations over the Sahel (Largerón et al. 2017). The decrease of  $T_{min}$  anomalies during HWmin events further continues until July (Fig. 3e), when the ITD is generally located north of the Sahel. This is possibly related to the establishment of a steady monsoon flow, as the presence of water vapor prevents strong nighttime cooling and tends to dampen nighttime temperature fluctuations (Guichard et al. 2009; Slingo et al. 2009). By contrast,  $T_{max}$  anomalies during a HWmax (Fig. 3d) are slightly higher in June and July, around the West African monsoon onset (Ali et al. 2003; Sultan et al. 2003), than in May. This is consistent with the increasing  $T_{max}$  variability during the early monsoon. Indeed, in the early monsoon phase, rain events cause sharp drops in  $T_{max}$  (Guichard et al. 2009; Schwendike et al. 2010). These  $T_{max}$  drops last for several days after the rain and are mainly due to jumps in surface evaporative fraction (Köhler et al. 2010; Lohou et al. 2014). Such  $T_{max}$  fluctuations at that time are probably favored by heterogeneous rain events (Fitzpatrick et al. 2015) and frequent dry spells (Sivakumar 1992; Frappart et al. 2009). The impact of rain on the surface energy budget is thus likely to increase  $T_{max}$  variability in the early monsoon phase.

The seasonal fluctuations of  $T_{max}$ ,  $T_{min}$ ,  $T_{mean}$  and DTR averaged over HWmin and HWmax events are relatively close to their respective mean annual cycles (Fig. 3f to 3i). The hottest (highest  $T_{max}$ ) HWmax occur in May, around the  $T_{max}$  annual cycle peak in April-May, with 50% of HWmax having  $T_{max}$  above 42°C. Likewise, the hottest (highest  $T_{min}$ ) HWmin occur in June, concomitant with the  $T_{min}$  annual cycle peak in May-June, with 50% of HWmin having  $T_{min}$  greater than 28.5°C. Note however that the occurrence of HWmax (HWmin) events does not systematically imply that  $T_{min}$  ( $T_{max}$ ) is higher than its climatic value (Fig. 3g,h). As a result, the DTR tends to be well above its climatic value during HWmax events,

and well below it during HWmin (Fig. 3f). Finally, Tmax remains above the human body temperature of 37°C during the core Spring months April-May-June for both HWmax and HWmin (Figure 3g): above this threshold, the human body cannot dissipate heat with its environment and cool down (Basu and Samet 2002; Kovats and Hajat 2008; Mora et al. 2017). Thus, even if this detection method is not specifically designed for health impacts, the detected heat waves are expected to be dangerous for the population health.

The impact of the criteria used for the detection of heat waves can be seen in Figure 3: the 3-day criterion strongly shapes the heat wave duration (Fig. 3b), with many only just passing this value (47% of HWmin and 44% of HWmax last 3 days). On the contrary, the detection method is qualitatively less sensitive to the spatial criterion (Fig. 3c) and to the 90<sup>th</sup> percentile threshold (Fig. 3d,e) as the two associated characteristics are far above the chosen thresholds. This indicates that Sahelian heat waves tends by essence to be large-scale events corresponding to large deviations from the mean annual cycle of temperature.

On average over March to July, heat wave characteristics are generally not very strongly coupled. However, the correlations between Tmax and Tmin and between DTR-Tmin are significant at the 95% level, being respectively for HWmax (HWmin) 0.53 (0.78) and -0.72 (-0.55). A significant correlation between the area covered by heat waves and the duration of heat waves is also found in March: for both HWmax and HWmin, the correlation is close to 0.5. Note that over the Sahelian domain, the correlations between monthly-mean values of Tmax and Tmin and between monthly-mean values of DTR and Tmin are also significantly correlated for each month ( $r > 0.5$ ). This indicates that these couplings between Tmax and Tmin and between DTR and Tmin remain valid from the smaller scale of heat-wave event to monthly time scales.

410

411           As previously discussed, very few HWmax and HWmin events overlap in  
412 space and time. Nevertheless, about 20% of concomitant HWmax and HWmin  
413 events are larger than 20% of the Sahelian domain for more than 3 days. These  
414 events lead to particularly stressful periods for Sahelian societies. Such heat wave  
415 events occur about once every two years over the region, last 4.8 days on average,  
416 are slightly smaller in extent than their parent HWmin and HWmax ( $110 \times 10^4 \text{ km}^2$   
417 against  $118/126 \times 10^4 \text{ km}^2$ ) and reach a mean value of 3.5 (3.4) °C for Tmax (Tmin)  
418 anomalies, compared with 3°C for HWmax (HWmin). Tmax (Tmin) values of the  
419 overlapping heat waves are not significantly different from the HWmax (HWmin)  
420 values at the 95% level though.

## 421 **4. Sensitivity of heat wave characteristics to the** 422 **definition and dataset**

### 423 ***a.* Impact of the heat wave definition**

424           We assess the sensitivity of our heat wave definition by comparing our  
425 results (section 3) with those obtained with definitions that are often used in the  
426 literature (section 2c). The heat wave characteristics obtained with each definition  
427 are summarized in Figure 4 and in Table 1.

428

429           The 15DW set tests the impact of taking a 15-day moving window to define a  
430 seasonal-dependent temperature anomaly threshold, instead of a constant percentile  
431 over March-to-July. 15DW heat wave frequency of occurrence is now fairly constant  
432 throughout the season (Fig. 4a): indeed the use of a moving window for the

determination of the 90<sup>th</sup> percentile causes a fixed number of days to be extreme for each calendar day. Otherwise, other heat wave properties are not significantly modified, except for a small difference in the anomaly amplitudes (Fig. 4d,e): the temperature anomalies are now higher in March-April then lower in June-July. This is related to the stronger temperature variability in the early months, resulting in more heat waves found in these months with our own definition.

The NoFilter\_15DW is often used in the literature. As for 15DW, the frequency of occurrence of heat waves is almost constant throughout March to July. The NoFilter\_15DW heat waves last longer, are overall larger, and their temperature anomalies are smaller, while their mean Tmax, Tmin, and Tmean are higher (Fig. 4). Finally, as for 15DW and the Reference, the duration of both HWmin and HWmax also decreases markedly from March to June.

The NoFilter heat wave set is mainly driven by the annual temperature cycle and most heat waves occur near its marked peak, in April-May for Tmax and in May-June for Tmin, with very few heat waves in March and July. Essentially, using filtered temperatures tends to increase the heat wave temperature anomalies while using raw temperatures tends to increase the heat wave temperatures (see 15DW compared to NoFilter\_15DW and Reference compared to NoFilter in Fig. 4d,e,g,h); this demonstrates the result that there is no direct correspondence between the strongest intraseasonal and synoptic temperature fluctuations and the highest temperatures, the latter being more controlled by longer term variability.

On average over the whole Spring extended period, heat wave properties are not significantly sensitive to the chosen approach (see Table 1), except for temperature-related differences that are directly linked to the approach. Finally, the percentile based on a long fixed window results in a steady seasonal distribution

over the intensities, while the percentile based on a short moving window causes a steady seasonal distribution over the occurrence, with the possibility of having a wide range of heat wave intensities from extreme heat waves to less extreme warm spells. Thus the choice of approach used to detect a heat wave is important, and ideally it should be driven by the targeted questions and applications. For instance, our “meteorological” approach favors the selection of heat waves of close intensities (in terms of temperature anomaly), and this choice is well suited for further composite studies (Roehrig et al. 2011; Poan et al. 2013). The connectedness constraint should also be helpful for heat wave tracking analyses. More broadly, some applications in agricultural and health sectors may require additional information in the heat wave detection, for instance soil moisture, atmospheric humidity or apparent temperature (such as in the National Oceanic and Atmospheric Administration (NOAA) heat index, [http://www.nws.noaa.gov/om/heat/heat\\_index.shtml](http://www.nws.noaa.gov/om/heat/heat_index.shtml)), which are currently not taken into account in the indices discussed above.

## **b. Sensitivity to the meteorological dataset**

For this study BEST is our reference dataset. In this section, the sensitivity of heat wave properties to the dataset is explored, by applying the same methodology on three meteorological reanalyses, namely ERA-Interim, NCEP2 and MERRA.

As the meteorological reanalyses only cover 1979-present, heat wave detection is restricted to their common period 1979-2012. BEST heat wave characteristics are very similar when detected over this shorter period (Fig. 5), with overall no significant difference at the 95% level for the mean morphological and temperature-related characteristics (except for a small increase of 0.2°C for HWmin Tmin anomalies).

The four products have distinct temperature distributions and annual cycles (see Appendix A), which induces differences between heat wave properties detected with one or the other dataset. Their average properties are summarized in Table 1.

For HWmax events, the frequency of occurrence is slightly lower in ERA-Interim compared to BEST, and much lower in NCEP2 and MERRA, by 40 and 60% respectively (Fig. 5a). In contrast, the frequency of occurrence of HWmin events is not significantly different between BEST, ERA-Interim and MERRA. Nevertheless, all datasets capture the annual cycle of BEST heat wave frequency of occurrence documented above, i.e., that the further into the Spring season, the smaller the probability of heat wave occurrence and the shorter these heat waves (not shown). Only ERA-Interim has a different behavior for HWmax events, which are most frequent in July. This appears to be linked to monthly differences in the temperature anomaly variances: indeed, for BEST, NCEP2 and MERRA they slowly decrease from March to July whereas the ERA-Interim variances increase from June on (see Appendix A).

The mean duration of HWmax events is similar in all reanalyses compared to BEST, in terms of distribution (Fig. 5b) and on average at the 95% level. HWmin events have a similar behavior except for MERRA events that are overall longer.

Heat waves in the reanalyses cover smaller areas than in BEST by approximately  $22 \times 10^4$  km<sup>2</sup> (Fig. 5c). BEST temperatures are constructed using a kriging regression method over station observations and are therefore quite sensitive to the density of the observational network. It is possible that the weak density of stations over the Sahel tends to smooth BEST temperatures (Rohde et al. 2013). In contrast, reanalyses with their higher resolution grids can generate smaller scale structures, which are more likely to produce spatially smaller heat waves.

All reanalyses also simulate stronger HWmax events than BEST (Fig. 5d). Tmax anomalies of HWmax are 0.6°C higher in ERA-Interim and 1.5°C higher in NCEP2 and MERRA. By contrast, Tmin anomalies of HWmin are rather consistent across the datasets, except for NCEP2 which strongly overestimates their intensity (on average 6.2°C compared to roughly 3°C). This shift is in direct relation with the Tmin anomaly variance of NCEP2 which reaches more than twice the variance of the other datasets (Fig. A1e and A2e).

The analysis of the temperature distribution discussed in Appendix A indicates that NCEP2 and ERA-Interim have a cold bias in Tmax while MERRA has a warm bias. NCEP2 has a very strong Tmin bias (up to -3°C). As a result, heat wave temperatures mostly follow the dataset mean temperature biases (Fig. 5g to 5i), except for HWmin Tmin in NCEP2 for which the cold bias is compensated by an overly strong high-frequency variability of Tmin.

In summary, heat wave characteristics are quite sensitive to the meteorological product used to detect them. The main differences seem to arise from the nature of the dataset considered (model versus interpolated local observations), and from the different biased temperature background. The former affect heat wave size and duration while the latter drives differences in heat wave temperatures. Both the synoptic and intraseasonal variability of reanalysed temperatures, especially for NCEP2, affect the occurrence of the heat waves. Finally, our results show that care should be taken when choosing a dataset for heat wave studies, especially over regions where in-situ observations are scarce, because differences between some basic heat waves characteristics can be quite large. Overall, ERA-Interim appears to be the best suited meteorological reanalysis to study heat waves when compared with local and gridded observations over the Sahel.

## 5. Long-term evolution of heat waves since 1950

Since 1950, temperatures have strongly increased in Spring over the Sahel. In this section, we analyze the links between this climatic trend and heat wave trends, with two complementary approaches.

### *a.* Event-based approach

The long-term linear trends (1950-2012) of the various heat wave properties are summarized in Table 2. HWmax event duration and area do not show any significant trend over the period, while their frequency of occurrence has slightly increased by 0.22 heat wave per decade. The area covered by HWmin events has significantly increased by 1% ( $3 \times 10^4$  km<sup>2</sup>) per decade since 1950, while there are no significant trends for their frequency of occurrence and their duration. The HWmax and HWmin intensity, as measured by their respective temperature anomalies, do not show any significant or strong trend either. In contrast, heat wave mean minimum, maximum and daily averaged temperatures significantly increased between 1950 and 2010, from 0.27 to 0.5°C per decade depending on the heat wave type or the considered temperature variable. Heat wave Tmin increased faster than the corresponding Tmax, about 0.5°C/decade for Tmin compared to roughly 0.3°C/decade for Tmax. The fact that Tmin increased faster than Tmax is consistent with the trends found by Guichard et al. (2015) in the Sahel. More broadly, this result has been highlighted worldwide and might be related for a part to an increase in the cloud cover (Karl et al. 1993; Easterling et al. 1997).

From 1950 to 2010, the long-term temperature trend over the Sahel is highly variable from month to month (Guichard et al. 2015). In April and May, monthly mean temperatures exhibit the most robust linear trend of around +0.3°C/decade, and

559 these are also the hottest months of the year. Therefore, only April and May are  
560 considered here to compare heat wave temperature trends to the mean Sahelian  
561 trend. Figure 6 shows the time series of April-May minimum and maximum  
562 temperature trends over the Sahel domain and their counterparts for the detected  
563 heat waves. A linear regression indicates that Sahel April-May mean maximum  
564 temperatures trends are equal to  $+0.25 \pm 0.09^{\circ}\text{C/decade}$  (95% confidence level),  
565 while the minimum temperature trend reaches  $+0.32 \pm 0.08^{\circ}\text{C/decade}$ . Even  
566 though this is consistent with a mean temperature trend in April-May of  
567  $0.3^{\circ}\text{C/decade}$ , this emphasizes different rates of increase for minimum and  
568 maximum temperature. HWmax event maximum temperatures mostly follow the  
569 increase of mean maximum temperature with a trend of  $0.29 \pm 0.14^{\circ}\text{C/decade}$ , and  
570 HWmin event minimum temperatures evolve approximately at the same rate as  
571 mean minimum temperatures ( $+0.37 \pm 0.22^{\circ}\text{C/decade}$ .) Thus the long-term  
572 evolution of heat waves over the Sahel appears to be mainly driven by the  
573 background temperature trend. Changes in synoptic and intraseasonal variability, if  
574 any, do not significantly impact heat wave temperature trends.

575         The link between heat wave trends and regional or global temperature  
576 trends has been largely addressed in the literature. For instance, Russo et al. (2014)  
577 argued that the global surface area impacted by heat waves significantly increased  
578 in the last decades. Gershunov and Guirguis (2012) found positive trends of heat  
579 wave magnitudes over 1950-2012. They also reported that the California inland  
580 desert heat wave temperatures are increasing less rapidly than the mean  
581 temperature. Argüeso et al. (2016) showed that globally the mean climate warming is  
582 responsible for most of the heat wave changes in the next century except for Europe  
583 and North America, in agreement with Schoetter et al. (2015) for Europe. In the

tropics, the climate warming is associated with a shift of the temperature distribution (Argüeso et al. 2016; Déqué et al. 2016), which is consistent with our results.

The linear trends over 1979-2012 of the four datasets (subsection 4b) are displayed in Table 2. The smaller number of heat waves in addition to the reduced time period are likely to increase the odds of a non-significant value, and the results must be taken with care. The main result is that, when significant, the Tmax, Tmean and Tmin show a positive trend. Conversely, for HWmin, there is a significant diminution of the area covered when using NCEP2 and MERRA. The spread of climatological trends estimated with these reanalyses is likely to be at play in the heat wave trends: Tmax climatological trends range from +0.3 in ERA-Interim to +0.55°C/decade in MERRA and Tmin trends from +0.3°C/decade in MERRA to +0.55 in NCEP2 (Fig. A3).

The heat waves detected in the present work are Lagrangian objects and therefore the analysis of the trends of some of their properties raises some questions. In an environment with spatial temperature gradients, heat wave temperature trends could involve shifts in the areas impacted by the heat wave in association with possibly different climatological trends over these areas. It would thus depend on the spatial pattern of the mean Tmin and Tmax long-term changes which are shown in Figures 7a,b. Indeed those climatological trends are spatially-dependent (Guichard et al. 2012; Fontaine et al. 2013; Guichard et al. 2015; Moron et al. 2016): both Tmin and Tmax linear trends are higher over Mauritania, Mali, and northern and western Niger, and decrease to the south towards the Guinean coast and to the very east over Chad. Hence the spatial and temporal distribution of the heat waves can influence the above heat wave trends. To better assess the role of these distributions, we weighted the climatological trend by the total number of heat

wave days for each grid point (not shown): thus an area that is affected by a great number of heat wave days will contribute more than an area affected by a lower number. In practice HWmax and HWmin are located mostly in the eastern part of the Sahelian domain, however the weighted climatological trends are unchanged. This non-homogeneous spatial distribution of the heat waves can also be time-dependent, so that heat wave temperature trends are then computed over slightly different climates. To avoid the issues linked to the Lagrangian approach, in the next section we investigate another option that uses a Eulerian approach to study the trends.

## **b. Local Eulerian approach**

Trends can also be computed for each grid-point, by considering the annual mean temperature for the days when heat waves occur at that grid-point. The selection of heat waves over the Sahelian domain leads to retain fewer heat waves at the edge of the Sahelian domain thus the sample is substantially reduced. To avoid these edge effects, all heat waves detected over the whole African domain are accounted for, not only those overlapping over 20% of the Sahel domain. The maps of significant linear trends are shown in Figures 7c,d.

Tmin trend of HWmin events is mostly uniform over the Sahel, reaching +0.4°C/decade (Fig. 7d). It is slightly lower over Burkina Faso and southern Mali as well as over northern Chad, where the trends there are below +0.3°C/decade. Overall Tmin trends of HWmin events are close to the climatological April-May trends, or slightly stronger, particularly over the south-east part of the Sahel (Fig. 7f): HWmin are thus warming at the same rate or slightly faster than the mean regional climate. Tmax trend of HWmax events is maximum over Mauritania, northern Mali and northern Niger, reaching +0.4°C/decade (Fig. 7c). It is minimum over central

Niger and central Chad. There the trend is slightly weaker than the mean long-term warming (Fig. 7e) which indicates that HWmax events intensify less quickly than the mean climate. This could be interpreted as a saturation effect for maximum temperatures whose distributions are negatively skewed (Fig. A1d and A2d) and which are already very high over the region during HWmax events (e.g., it could involve physical mechanisms operating in the surface energy balance at high temperature). Interestingly, a similar result was noted by Gershunov and Guirguis (2012) over the Californian desert.

The differences between heat wave and climate trends range between -0.2 and 0.2°C/decade, which is close to the confidence interval of the trends themselves. Therefore, temperature trends at the climate and heat wave scales over the Sahel are mostly similar, with some spatial particularities that need to be further assessed.

## 6. Conclusion

This paper introduces a new heat wave detection methodology that comprises four different steps: a temperature filtering to focus on specific temporal scales; the determination of a temperature extreme threshold based on a March-to-July window 90<sup>th</sup> percentile; the application of a spatio-temporal constraint and finally the selection of a particular geographic domain.

The filtering process enables us to focus on a specific type of heat waves, without mixing different temporal scales. Here, we focused on heat waves of synoptic to intra-seasonal scales and thus we decoupled heat wave events from the annual cycle and long-term temperature variabilities. The use of a fixed window provides information on the seasonal evolution of the heat wave occurrences. The spatio-temporal constraint selects spatially and temporally coherent heat waves

(here they last at least 3 days and cover more than  $60 \times 10^4 \text{ km}^2$ ). The final step of selecting a particular domain allows this heat index to be used over any region.

This heat index was applied separately to daily maximum and minimum temperatures ( $T_{\text{max}}$  and  $T_{\text{min}}$ ) of the observational-based BEST dataset. We found an average of 3.3 “ $T_{\text{max}}$  heat waves” ( $\text{HW}_{\text{max}}$ ) and 2.9 “ $T_{\text{min}}$  heat waves” ( $\text{HW}_{\text{min}}$ ) per year. Both types of heat waves last on average around 5 days, cover roughly  $120 \times 10^4 \text{ km}^2$  with a temperature anomaly of  $+3^\circ\text{C}$ . In May, the mean  $T_{\text{max}}$  ( $T_{\text{min}}$ ) of  $\text{HW}_{\text{max}}$  ( $\text{HW}_{\text{min}}$ ) reaches up to  $42^\circ\text{C}$  ( $28^\circ\text{C}$ ) or more. The  $\text{HW}_{\text{min}}$  areas are slightly smaller than the  $\text{HW}_{\text{max}}$ . Concomitant  $\text{HW}_{\text{max}}$  and  $\text{HW}_{\text{min}}$  events happened only one fifth of the time. This result supports the decision to separately analyze maximum and minimum temperatures in the Sahelian region.

Heat waves also become shorter and less frequent from March to July.  $\text{HW}_{\text{min}}$  events are particularly rare in June-July. In March-April, heat wave temperature anomalies are stronger than those in June-July, a consequence of the temperature anomaly variance distribution of BEST.

There was no strong climatological trend of heat wave occurrences over 1950-2012. However, their  $T_{\text{max}}$  ( $T_{\text{min}}$ ) significantly increased from 1950 to 2012, by  $1.6^\circ\text{C}$  for  $\text{HW}_{\text{max}}$  ( $2.6^\circ\text{C}$  for  $\text{HW}_{\text{min}}$ ). This warming is consistent with a mean shift of the temperature distribution, in line with the results of Argüeso et al. (2016) in the tropics, e.g., the heat waves are not intrinsically hotter, rather, they reflect the warming climate. In the northern Sahel though, we found that the climatic warming trend is stronger than the heat-wave trend for the  $T_{\text{max}}$ , as also highlighted by Gershunov and Guirguis (2012) over Californian deserts.

The results are quite similar when the percentile is computed over a 15-day moving-window, except for differences over the seasonal occurrences that are directly linked to methodological choices. The constant percentile led to a steady

temperature anomaly distribution throughout the season while the moving-window produced a steady seasonal occurrence distribution, leading to a wide range of heat wave intensities. Over a moving-window without the filtering process, we found that heat waves were longer and larger. As expected, heat waves are also becoming more frequent by one per decade when raw instead of filtered temperature are used.

The heat index was also computed similarly with temperatures from three meteorological reanalyses, namely ERA-Interim, NCEP2 and MERRA, over 1979-2012. The heat waves were smaller than for BEST; this could be related to the different nature of the datasets (observationally-based versus model) – the heat wave sizes in reanalyses are not smaller for the finer grid though. Inherent biases between the distributions of climatological means and variances resulted in significant differences in temperature-related heat wave characteristics. This notably affects Tmin anomalies in NCEP2 HWmin (they are 3°C higher on average) and to a lesser extent Tmax in MERRA HWmax, while temperature and temperature anomalies in both heat wave types are much closer to BEST in ERA-Interim.

Perkins (2015) identified three potential drivers of heat waves: synoptic systems, soil moisture - atmosphere feedbacks and larger-scale dynamics. Fontaine et al. (2013) studied the latter and suggested Rossby waves may play a role in the forcing heat waves. The second potential driver is unlikely here since soil moisture is very low during Springtime in the Sahel. However, this does not preclude the significance of other mechanisms of surface-atmosphere interaction in this region. For instance, Largeron et al. (2017) recently described a major water vapor impact on nighttime temperature in a Sahelian heat wave case study.

More generally, further studies are necessary to analyze the meteorological situations associated with Sahelian heat waves and to understand how physical processes distinctly shape nighttime and daytime temperatures during these events.

711 The present set of detected heat waves, combined with observations and dynamical  
712 fields from reanalyses, should be useful for such purpose. This would allow for  
713 studying composites of these events, for instance at a given location we could define  
714 composites from the time sequences associated with the passages of heat waves.  
715 For the locations where in-situ data are available (e.g., those from the AMMA-  
716 CATCH network, Lebel et al. 2009), observations might also be used to analyze the  
717 dynamic and thermodynamic characteristics of the events at small scale.

718 Further studies should also investigate the causes behind the distinct trends  
719 in  $T_{\max}$  for  $HW_{\max}$  and  $T_{\min}$  for  $HW_{\min}$ . In particular, the strong  $T_{\min}$  trend raises  
720 questions about its potential links with changes in atmospheric water vapor or cloud  
721 cover (Karl et al. 1993; Easterling et al. 1997). Although observations are scarce,  
722 they are valuable for exploring relationships between water vapor and nighttime  
723 temperature during heat waves in a more systematic way (Evan et al. 2015).

724 Finally, from a modeling perspective, previous studies (e.g., Roehrig et al.  
725 2013) point to a large spread in CMIP5 simulations of annual cycles and mean  
726 trends of temperatures over the Sahel. For heat waves specifically, our methodology  
727 applied to these simulations could document their ability to simulate heat waves.  
728 Moreover, as heat wave characteristics and trends may not be independent from the  
729 simulated mean climate and climatological trends in the Sahel, it would be valuable  
730 to analyze their links.

## **Aknowledgements**

This study is part of ANR project ACASIS (2014-2017, grant: ANR-13-SENV-0007). We thank the reviewers for their constructive comments and suggestions.

738

739

Table 1: Average heat wave properties obtained with our heat wave index

740

using the BEST dataset over 1950-2012 (the reference, first line), with other heat

741

wave indices, and with our heat wave index using BEST, ERA-Interim, NCEP2 and

742

MERRA over 1979-2012. The first and second values corresponds respectively to

743

HWmax and and HWmin properties. Bold indicate values that are significantly

744

different (Student's t test at the 95% level) from those obtained in the reference; bold

745

italic indicates values that are significantly different from BEST over 1979-2012 and

746

is used when comparing to various reanalyses (ERA-Interim, NCEP2, and MERRA).

Table 2: As Table 1, except for decadal trends of the heat wave characteristics over March to July. A trend is considered non significant (NS) if the p value is larger than 0.05.

## Figure captions

Figure 1: Illustration of the methodology used to define the heat index using the example of the maximum temperature index  $HI_{max}$  in 1992 at Hombori (its geographic position is indicated with a black dot in the lower panel). Each slot represents a step from the initial temperature to the final heat index. The red dots indicate the detection of heat waves at Hombori; black dots are drawn when there is a heat wave somewhere within the African domain. There are five heat waves in 1992. The first one in March HW1 did not affect Hombori (black dots but no red dots). The next one HW2 starts in an area including Hombori and then moves away. The spatial extend of third, HW3, is represented in the lower panel maps (red-colored area) and the gray crossed boxes indicate the Sahelian domain. There are only black dots and no red dots in f) as the heat wave is located over the east of the domain, far from Hombori.

Figure 2: Chronology of the heat waves for the heat index using maximum temperature on the left panel ( $HW_{max}$ , red) and minimum temperature on the right panel ( $HW_{min}$ , blue), using BEST dataset from 1950 to 2012. Each point indicates the occurrence of a heat wave for the corresponding day and year. The crosses indicate heat waves that are shared by both  $HW_{max}$  and  $HW_{min}$ , cover an area of at least 20% of the Sahelian domain and last at least three days.

Figure 3: Evolution of the morphological and thermodynamical characteristics of  $HW_{max}$  (red) and  $HW_{min}$  (blue) from March to July for the period 1950-2012

represented by percentile box plots. Climatological values smoothed by a moving average over 21 days are shown with gray lines in Figures 3f to 3i.

Figure 4: Same as in Figure 3 but for averaged characteristics of heat waves identified with different methodologies: Reference (black line); 15DW (light blue line); NoFilter\_15DW (green line); NoFilter (red line). Monthly characteristics computed over less than five heat waves are not plotted. In each panel, the curves on the left side refer to HWmax and those on the right side to HWmin.

Figure 5: Same as Figure 3 but over the whole period March to July for different meteorological products: BEST, ERA-Interim, NCEP2 and MERRA over the period 1979-2012 unless indicated.

Figure 6: Time series of April-May mean Tmax (top panel) and Tmin (bottom panel) for each year from 1950 to 2012 on average over the Sahelian domain (solid black lines) and over heat waves, namely Tmax of HWmax (solid red curve, top panel) and Tmin of Hwmin (solid blue curve, bottom panel); dotted-dashed lines correspond to the associated linear trends. Heat wave curves are discontinuous since heat waves do not occur every year. The Lagrangian approach is used to compute the heat wave trends.

Figure 7: Maps of climatological trends of (a) Tmax and (b) Tmin computed over April-May for 1950-2012; (c,d) same as (a,b) except for Tmax of HWmax heat waves and Tmin of HWmin heat waves and (e,f) the difference between climatological and heat wave trends ( $7e=7c-7a$ ,  $7f=7d-7b$ ). Crosses indicate grid points where differences are not significant at the 95% level.

799

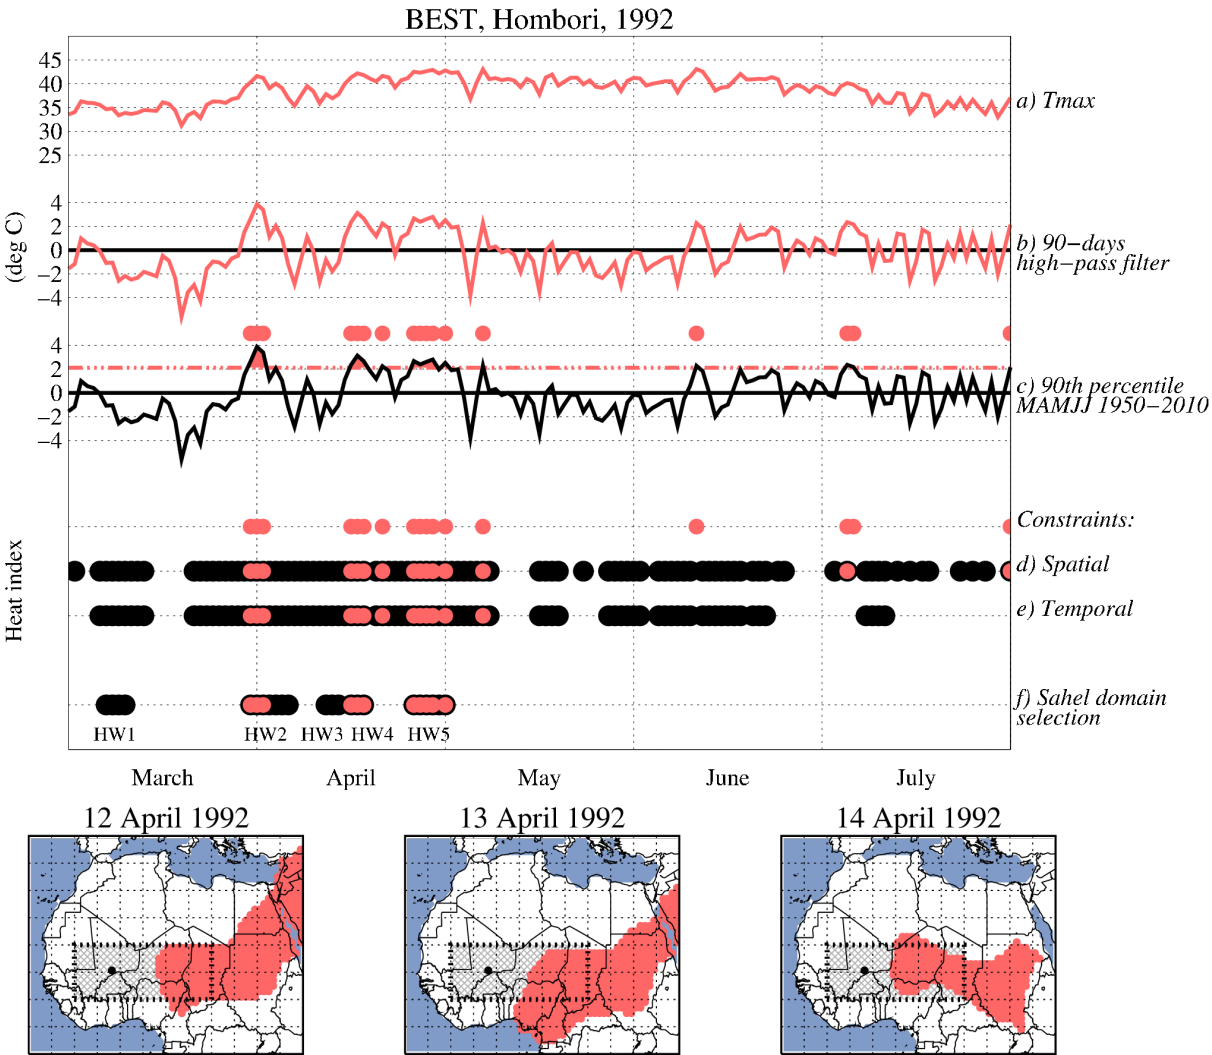

800 Figure A1: Statistical moments of the maximum and minimum temperature  
801 distributions of the observationally gridded dataset BEST, the reanalyses ERA-  
802 Interim, NCEP2 and MERRA, and the SYNOP station Hombori, Mali (15.33°N,  
803 1.8°E) over 1979-2010 by month and over the March-July (MAMJJ) period. The  
804 climatic trends are removed before computing the moments. The anomaly variances  
805 (Fig 1Ae,j) correspond to the variance of the anomaly temperatures computed with  
806 the 90-day high-pass filter. The years 1988, 1989 and 1990 have been removed  
807 because of inconsistencies in the Tmin of Hombori.

808

809 Figure A2: Same as Figure 1A but for BEST, ERA-Interim, NCEP2 and MERRA over  
810 the Sahelian domain [10°N 20°N] [-10°E 20°E] over 1979-2012. The climatological  
811 trends are removed before computing the moments.

812

813 Figure A3: Time series of Sahelian-mean Tmax and Tmin averaged over April-May.  
814 The correlation R between BEST and the datasets, the means and the linear trends  
815 of the four datasets over April-May 1950-2012 are shown in the insets. Crosses  
816 indicate trends that are not significant at the 95% level.

818

819 Figure 1: Illustration of the methodology used to define the heat index using the

820 example of the maximum temperature index  $H_{Imax}$  in 1992 at Hombori (its

821 geographic position is indicated with a black dot in the lower panel). Each slot

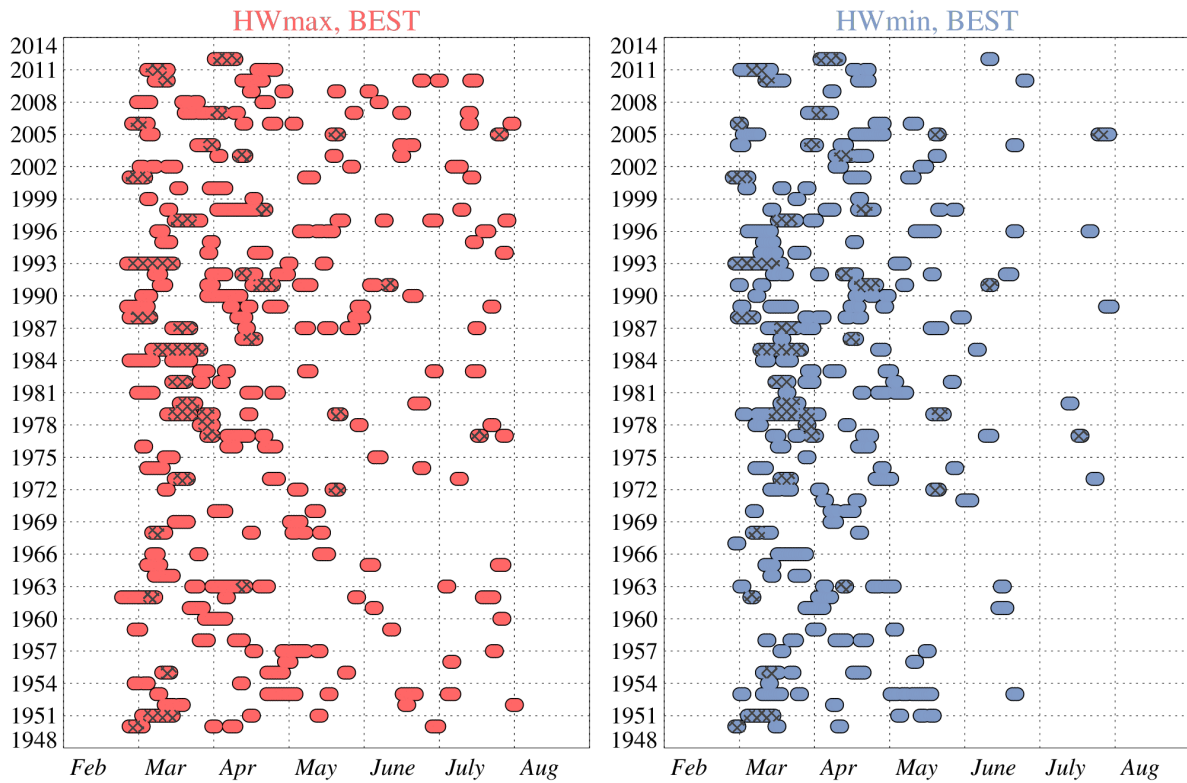

822 represents a step from the initial temperature to the final heat index. The red dots

823 indicate the detection of heat waves at Hombori; black dots are drawn when there is

824 a heat wave somewhere within the African domain. There are five heat waves in

825 1992. The first one in March HW1 did not affect Hombori (black dots but no red

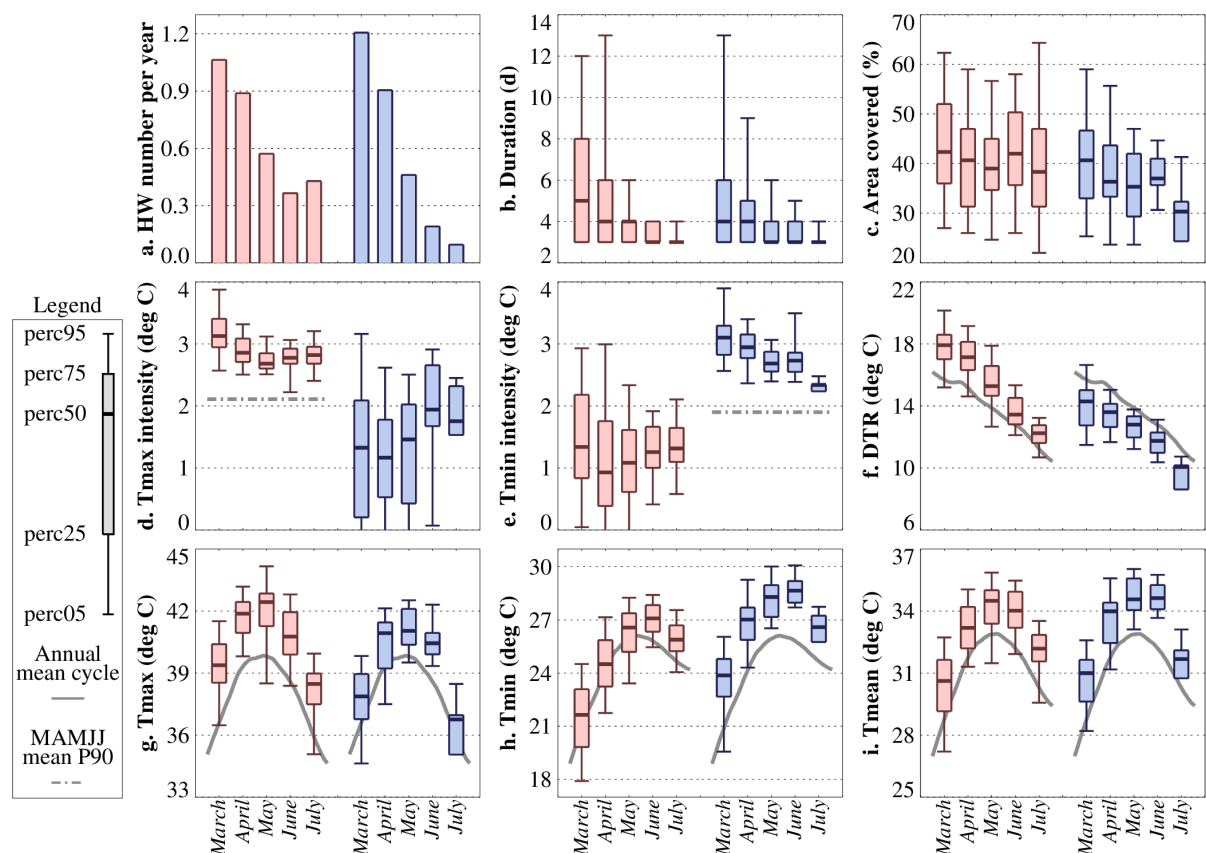

826 dots). The next one HW2 starts in an area including Hombori and then moves away.  
827 The spatial extend of third, HW3, is represented in the lower panel maps (red-  
828 colored area) and the gray crossed boxes indicate the Sahelian domain. There are  
829 only black dots and no red dots in f) as the heat wave is located over the east of the  
830 domain, far from Hombori.

831

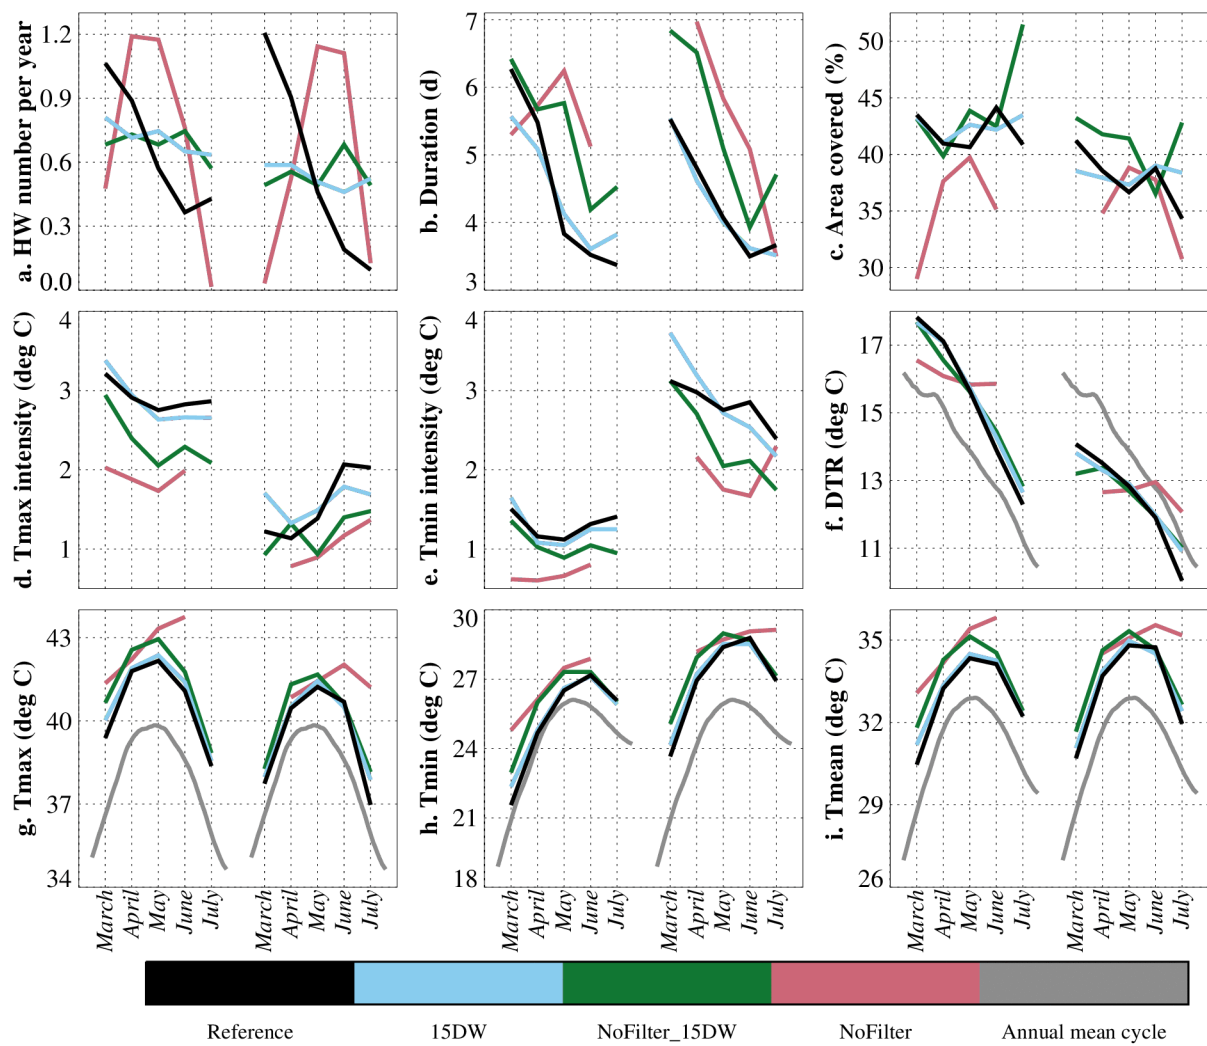

832 Figure 2: Chronology of the heat waves for the heat index using maximum  
 833 temperature on the left panel (HWmax, red) and minimum temperature on the right  
 834 (HWmin, blue), using BEST dataset from 1950 to 2012. Each point indicates the  
 835 occurrence of a heat wave for the corresponding day and year. The crosses indicate  
 836 heat waves that are shared by both HWmax and HWmin, cover an area of at least  
 837 20% of the Sahelian domain and last at least three days.

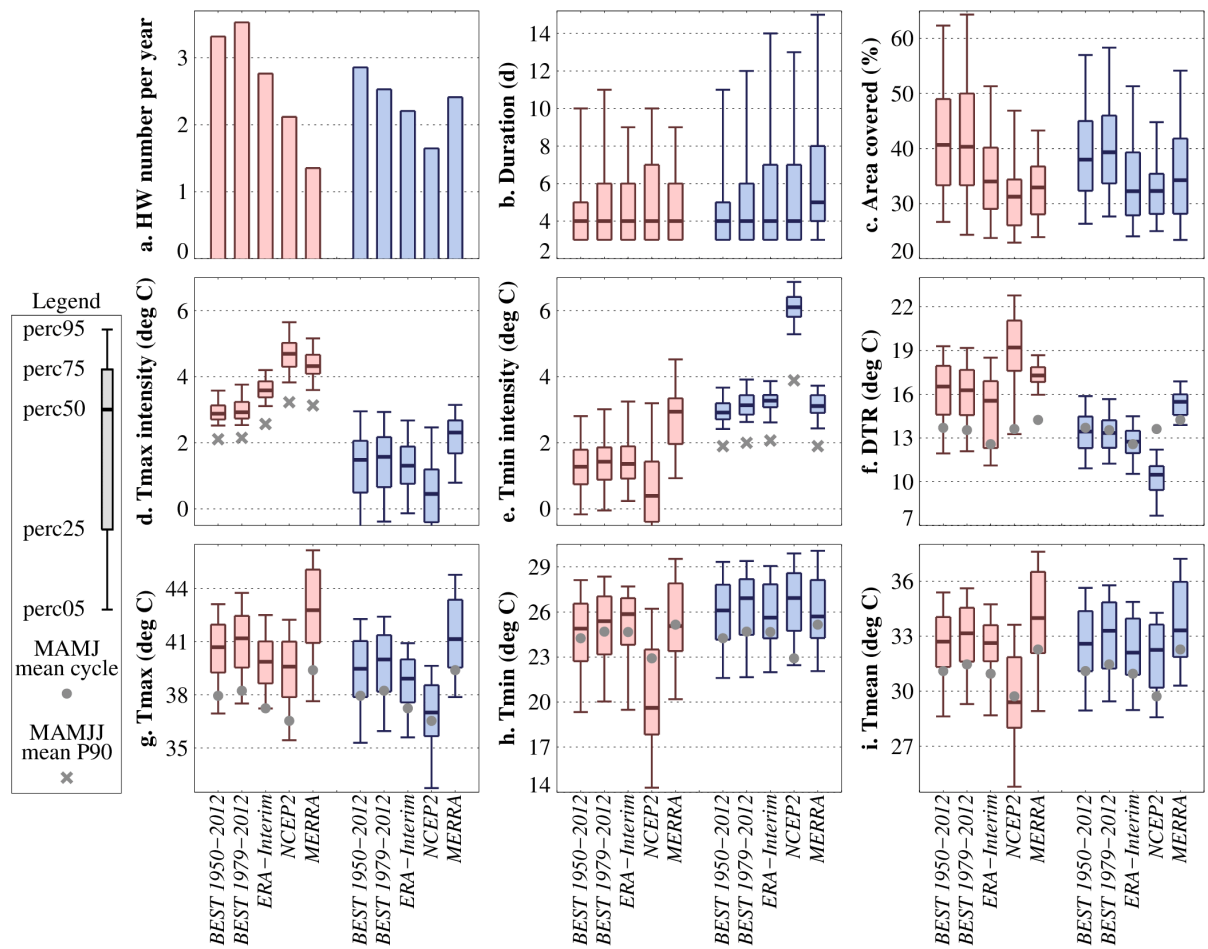

839

840 Figure 3: Evolution of the morphological and thermodynamical characteristics of  
841 HWmax (red) and HWmin (blue) from March to July for the period 1950-2012  
842 represented by percentile box plots. Climatological values smoothed by a moving  
843 average over 21 days are shown with gray lines in Figures 3f to 3i.

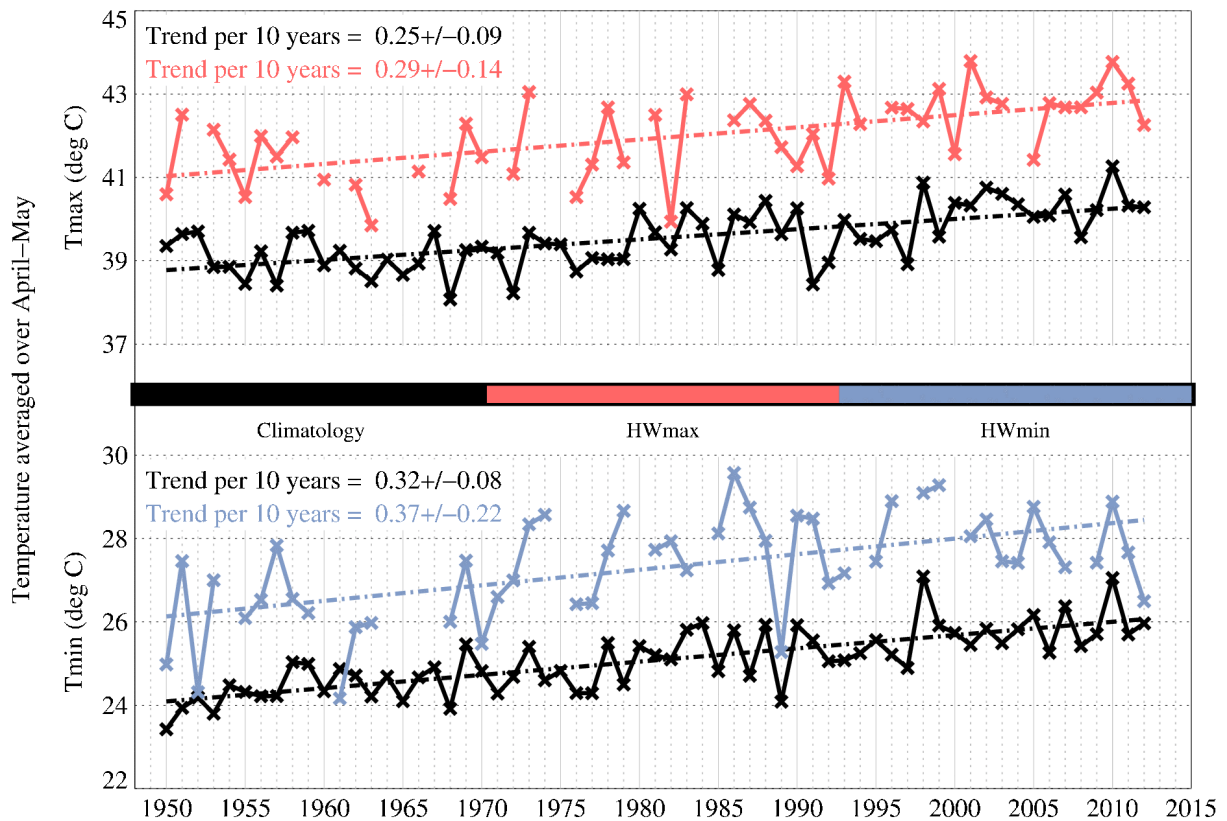

844

845 Figure 4: Same as in Figure 3 but for averaged characteristics of heat waves  
 846 identified with different methodologies: Reference (black line); 15DW (light blue line);  
 847 NoFilter\_15DW (green line); NoFilter (red line). Monthly characteristics computed  
 848 over less than five heat waves are not plotted. In each panel, the curves on the left  
 849 side refer to HWmax and those on the right side to HWmin.

850

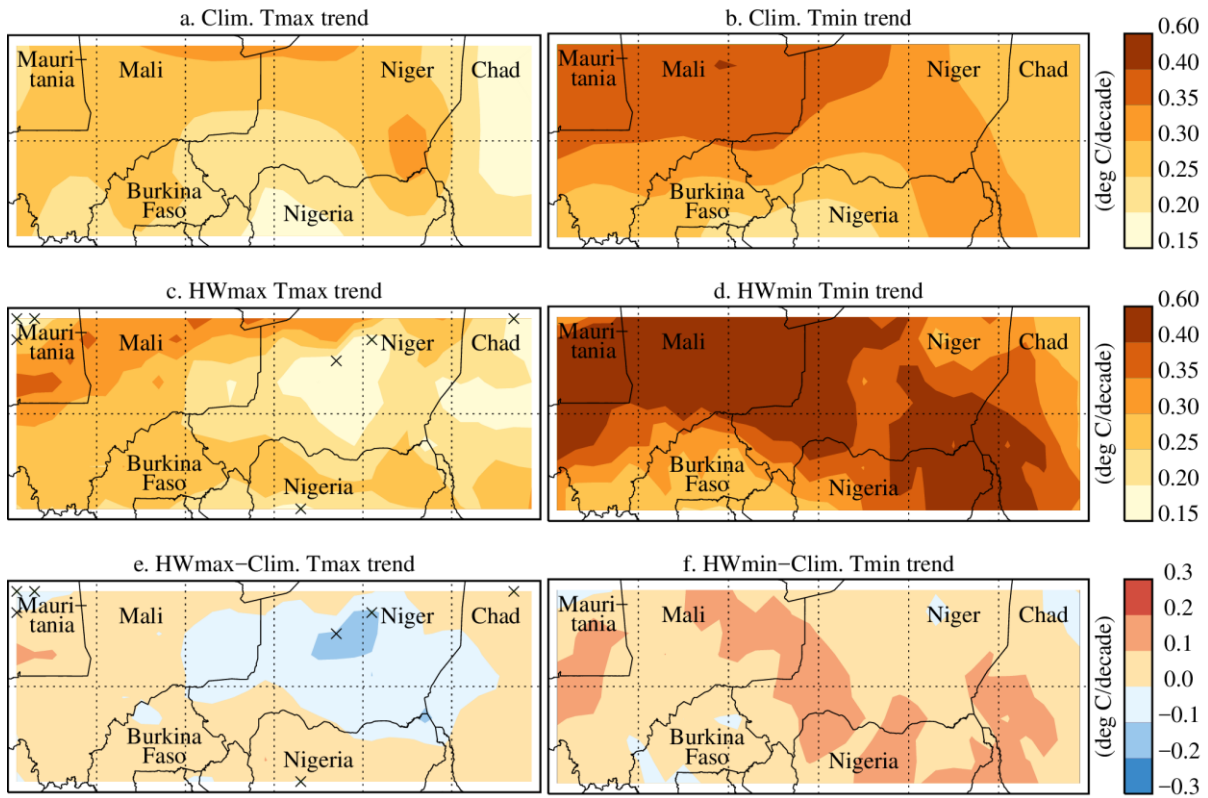

851 Figure 5: Same as Figure 3 but over the whole period March to July for different meteorological  
 852 products: BEST, ERA-Interim, NCEP2 and MERRA over the period 1979-2012  
 853 unless indicated.

854

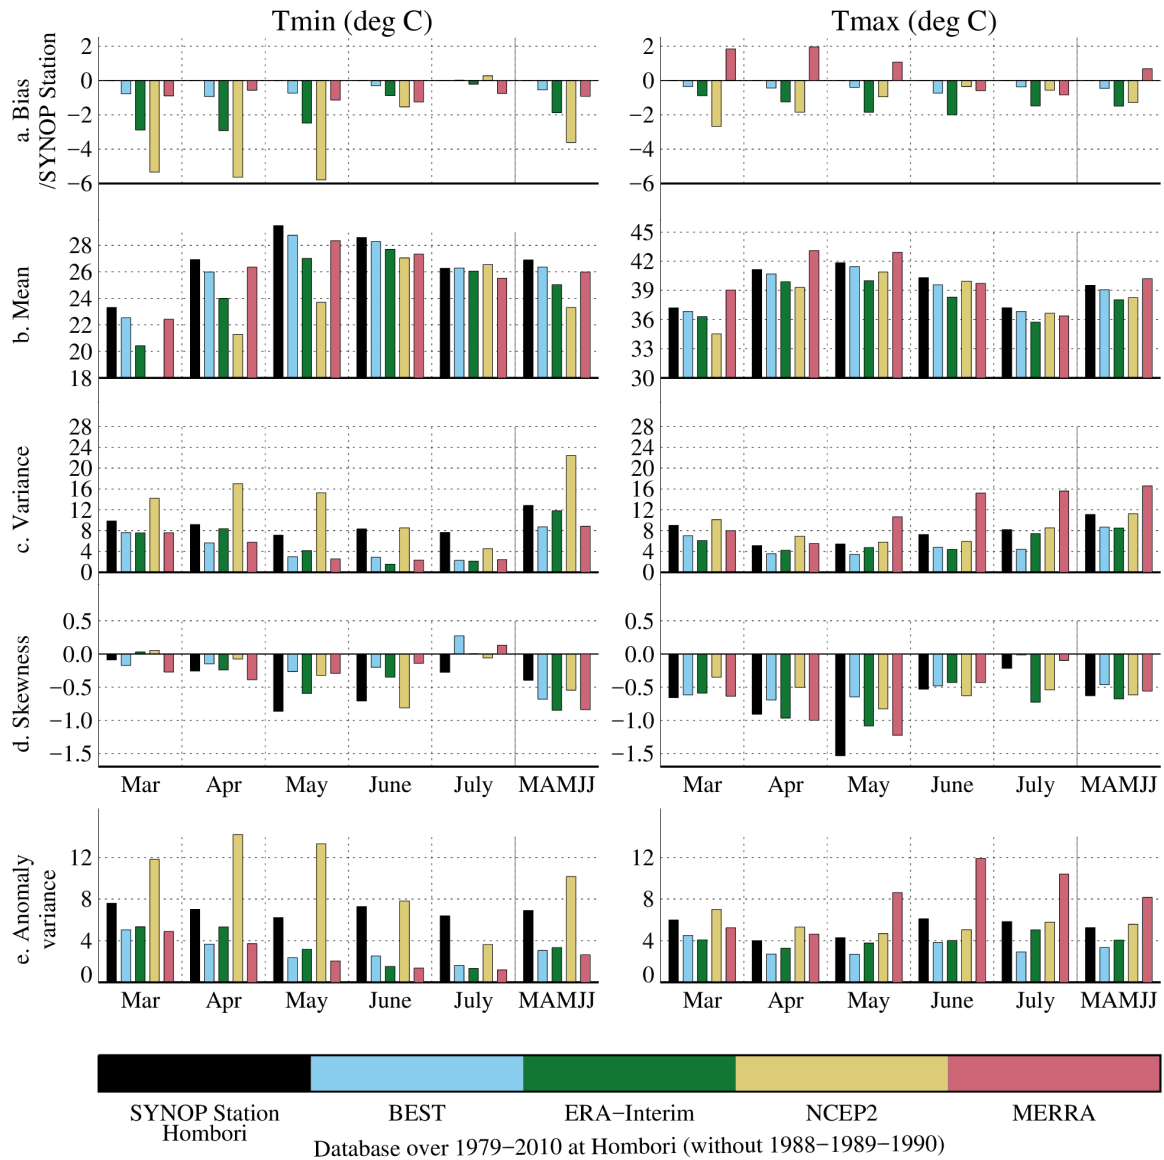

855 Figure 6: Time series of April-May mean Tmax (top panel) and Tmin (bottom panel)  
 856 for each year from 1950 to 2012 on average over the Sahelian domain (solid black  
 857 lines) and over heat waves, namely Tmax of HWmax (solid red curve, top panel) and  
 858 Tmin of Hwmin (solid blue curve, bottom panel); dotted-dashed lines correspond to  
 859 the associated linear trends. Heat wave curves are discontinuous since heat waves  
 860 do not occur every year. The Lagrangian approach is used to compute the heat wave  
 861 trends.

BEST, April–May, 1950–2012

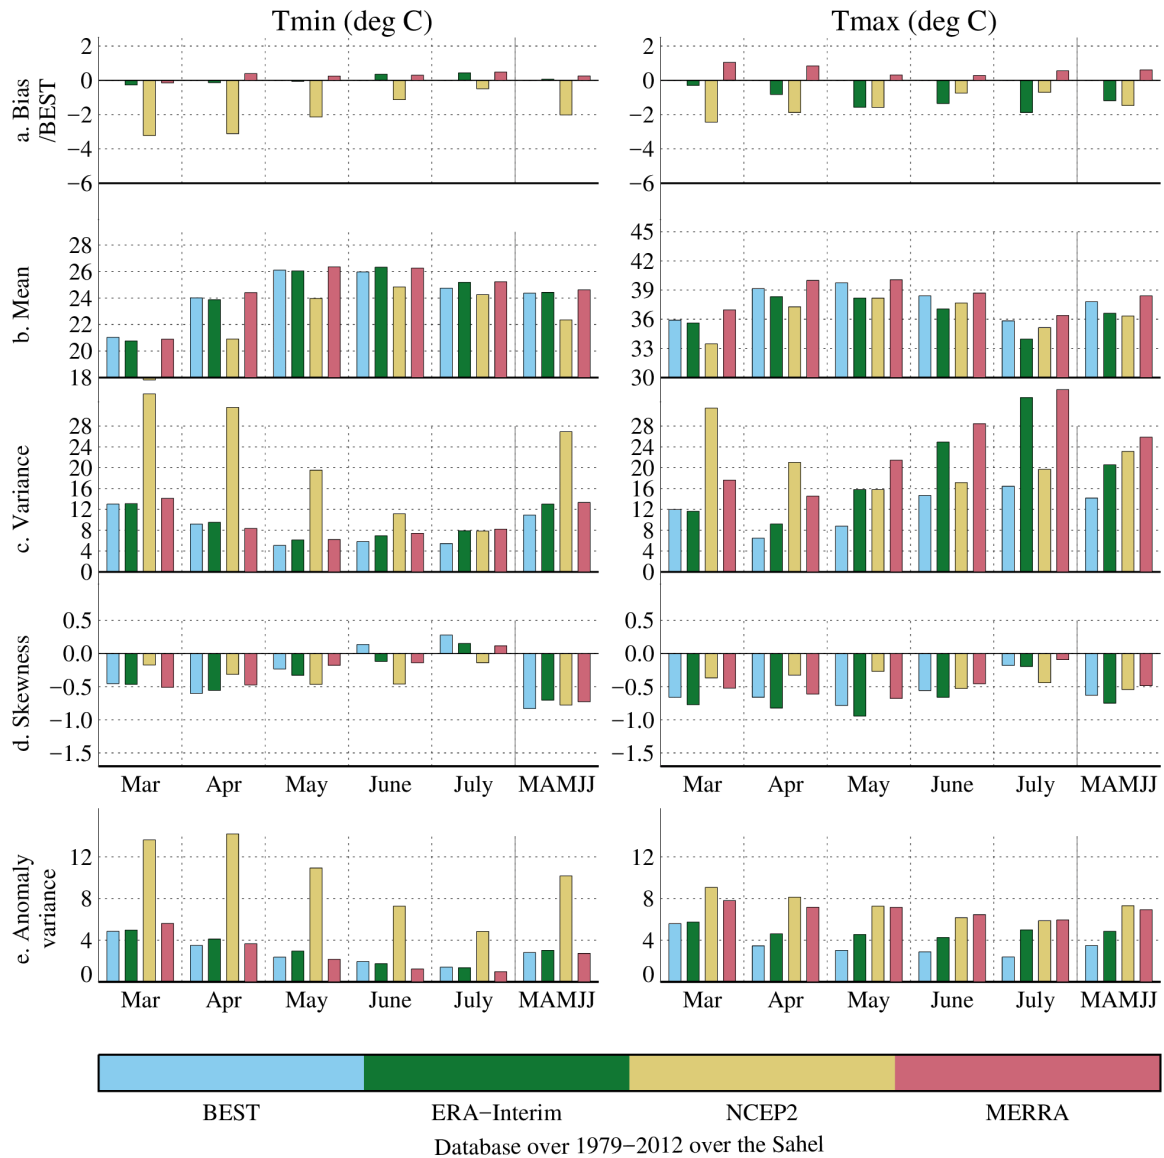

862

863 Figure 7: Maps of climatological trends of (a) Tmax and (b) Tmin computed over  
 864 April–May for 1950–2012; (c,d) same as (a,b) except for Tmax of HWmax heat waves  
 865 and Tmin of HWmin heat waves and (e,f) the difference between climatological and  
 866 heat wave trends ( $7e=7c-7a$ ,  $7f=7d-7b$ ). Crosses indicate grid points where  
 867 differences are not significant at the 95% level.

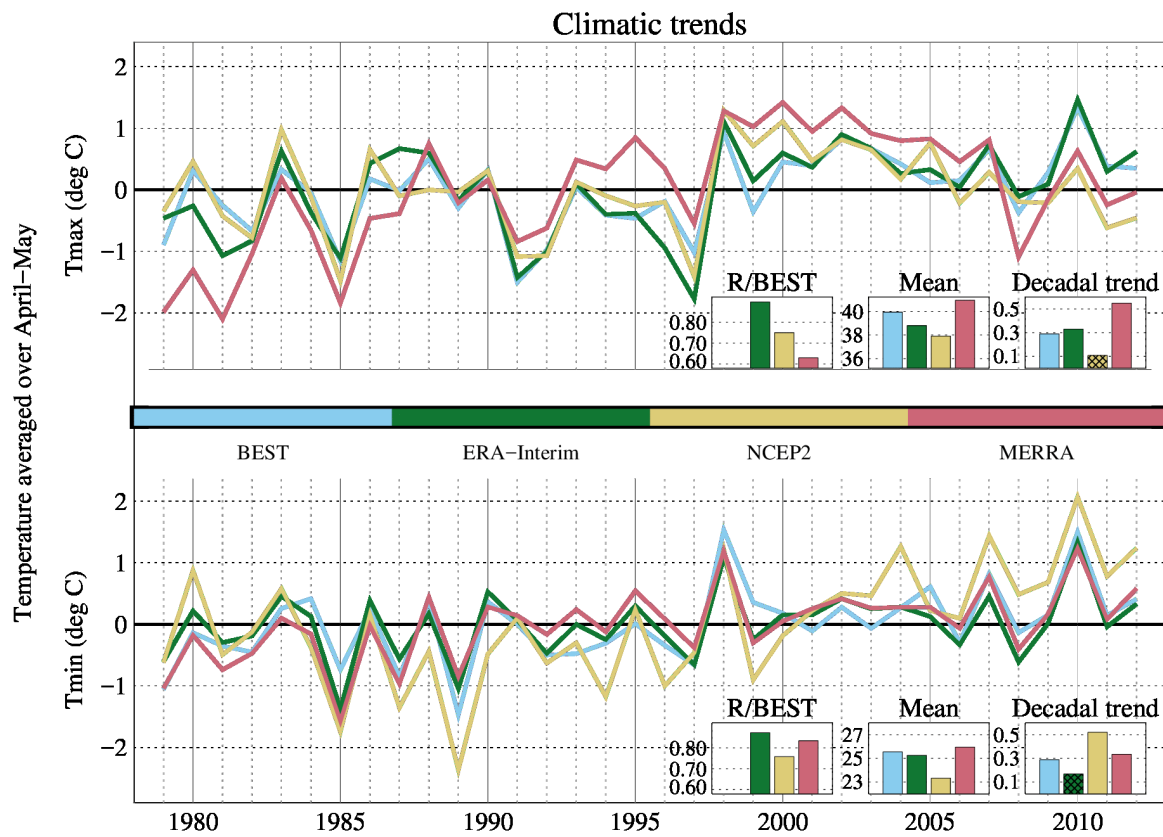

868

869 Figure A1: Statistical moments of the maximum and minimum temperature  
870 distributions of the observationally gridded dataset BEST, the reanalyses ERA-  
871 Interim, NCEP2 and MERRA, and the SYNOP station Hombori, Mali (15.33°N,  
872 1.8°E) over 1979-2010 by month and over the March-July (MAMJJ) period. The  
873 climatic trends are removed before computing the moments. The anomaly variances  
874 (Fig 1Ae,j) correspond to the variance of the anomaly temperatures computed with  
875 the 90-day high-pass filter. The years 1988, 1989 and 1990 have been removed  
876 because of inconsistencies in the Tmin of Hombori.

877

878 Figure A2: Same as Figure 1A but for BEST, ERA-Interim, NCEP2 and MERRA over  
 879 the Sahelian domain [10°N 20°N] [-10°E 20°E] over 1979-2012. The climatological  
 880 trends are removed before computing the moments.

881

882 Figure A3: Time series of Sahelian-mean Tmax and Tmin averaged over April-May.

883 The correlation R between BEST and the datasets, the means and the linear trends

884 of the four datasets over April-May 1950-2012 are shown in the insets. Crosses

885 indicate trends that are not significant at the 95% level.
